Certification of Programs for Secure Information Flow

Dorothy E. Denning and Peter J. Denning
Purdue University

This paper presents a certification mechanism for verifying the secure flow of information through a program. Because it exploits the properties of a lattice structure among security classes, the procedure is sufficiently simple that it can easily be included in the analysis phase of most existing compilers. Appropriate semantics are presented and proved correct. An important application is the confinement problem: The mechanism can prove that a program cannot cause supposedly nonconfidential results to depend on confidential input data.

Key Words and Phrases: protection, security, information flow, program certification, lattice, confinement, security classes

1. Introduction

Computer system security relies in part on *information flow control*, that is, on methods of regulating the dissemination of information among objects throughout the system. An information flow policy specifies a set of *security classes* for information, a *flow relation* defining permissible flows among these classes, and a method of *binding* each storage object to some class. An operation, or series of operations, that uses the value of some object, say x, to derive a value for another, say y, causes a *flow* from x to y. This flow is admissible in the given flow policy only if the security class of x flows into the security class of y.

Prior work on the enforcement of flow policies has concentrated on run-time mechanisms. One type of mechanism enforces a given flow policy by controlling processes' read and write access rights to objects: no process may acquire read access for an input object, or write access for an output object, unless the security class of every input flows into the security class of every output—even if some outputs depend on only a subset of the inputs. ADEPT-50 [30], the Case system [29], the MITRE system [3, 23], and the Privacy Restriction Processor [26] are of this type. These mechanisms are generally easy to implement because they make no attempt to examine the structure of a program. A second type of (more complex) mechanism accounts for program structures in order to determine flows between specific input and output objects. Fenton's data mark machine [10], the mechanism of Gat and Saal [13], and the surveillance mechanism of Jones and Lipton [19] are of this type. The surveillance mechanism employs a program transformation to insure that all flows are properly accounted for at run time. A detailed discussion of all these mechanisms can be found in [7].

This paper presents a compile-time mechanism that certifies a program only if it specifies no flows in violation of the flow policy. Besides the aesthetic attraction of establishing a program's security before it executes, a certification mechanism has important advantages. It can be specified directly in terms of language structures, which facilitates its comprehension and its proof of correctness. It greatly reduces the need for run-time checking. It does not impair a program's execution speed. (See also [23]).

Prior certification does not completely eliminate the need for run-time checking. Run-time support is needed to raise the tolerance against hardware malfunctions and other threats to the integrity of certified

programs. It is needed to verify that computed addresses remain in the ranges assumed for them during certification. It is needed to control covert channels, which allow flows outside the storage objects of the system.

2. Lattice Model of Information Flow

We give a brief review of the flow model on which the certification mechanism is based [6, 7]. The model generalizes earlier work as reported in [3, 9, 10, 11, 23, 26, 29, 30].

2.1 Policy Description and Properties

A flow policy can be represented by $\langle S, \rightarrow \rangle$, where S is a given set of security classes and $\rightarrow$ is a flow relation specifying permissible flows between pairs of classes. Each storage object x – e.g. constant, scalar variable, array, or file – is assigned (bound) to a security class, denoted by underbar, $\underline{x}$. The notation $x \rightarrow \underline{y}$ thus means that a flow from object x to object y is permissible in the flow policy. We will suppose the binding of each object to a security class is *static* and can be determined from the declarations contained in a program.

Under the reasonable assumptions that there is a finite number of security classes, that the flow relation is reflexive (i.e. $\underline{x} \rightarrow \underline{x}$ is always permissible), and that the flow relation is transitive (i.e. $\underline{x} \rightarrow \underline{y} \rightarrow \underline{z}$ implies $\underline{x} \rightarrow \underline{z}$), we may suppose that $\langle S, \rightarrow \rangle$ is a lattice. This means that, corresponding to any pair of classes, there are unique upper and lower bound classes. If $\langle S, \rightarrow \rangle$ is not a lattice, it may be transformed into one by adding new classes as necessary without changing the flows among the original classes [8]. The lattice properties are exploited to construct an efficient certification mechanism.

The symbols $\oplus$ and $\otimes$ denote, respectively, the associative and commutative *least upper bound* and *greatest lower bound* operators of the lattice $\langle S, \rightarrow \rangle$ [4, 28]. The least upper bound is defined so that $\underline{x}_i \rightarrow \underline{y}$ for $i = 1, \ldots, m$ is equivalent to the relation $\underline{x}_1 \oplus \cdots \oplus \underline{x}_m \rightarrow \underline{y}$. It can be envisaged as requiring that flows from various operand classes must pass through a single common class en route to a given result class. The greatest lower bound is defined so that $\underline{x} \rightarrow \underline{y}_j$ for $j = 1, \ldots, n$ is equivalent to the relation $\underline{x} \rightarrow \underline{y}_1 \otimes \cdots \otimes \underline{y}_n$. It can be envisaged as requiring that flows from a given operand class must pass through a single common class en route to various result classes. There is a *highest* class H, which is the least upper bound of all classes, and a *least class* L, which is the greatest lower bound of all classes.

All unnamed programming language constants are members of L. This assumption is reasonable since the flow of an ordinary constant, say "99," into a variable, say x, puts in x no information about any other object. Only when "99" is known to be the value of an object y for which $\underline{y} \not\rightarrow \underline{x}$ must its flow be prevented; but this is done by restricting the flow from y, not from "99."

Figures 1 and 2 illustrate lattices that arise frequently in practice. Figure 1 is a linear "priority lattice" on n classes $0, 1, \ldots, n-1$, where $L = 0$ and $H = n - 1$. This lattice applies to the simple confinement problem with classes nonconfidential (0) and confidential (1) [10] and to the common military security problem with classes unclassified (0), confidential (1), secret (2), and top secret (3) [30]. Figure 2 shows a more complex "property lattice" representing the immediate inclusions among all 2^n subsets of $n = 3$ properties represented as bit vectors. It generalizes easily to any value of n and is used in systems where information may flow only to a security class having at least the same properties as the originating class [3, 23, 29, 30].

2.2 Flow

Information *flows* from object x to object y, denoted $x \Rightarrow y$, whenever information stored in x is transferred to, or used to derive information transferred to, object y. A program statement *specifies* a flow $x \Rightarrow y$ if execution of the statement could result in a flow $x \Rightarrow y$.

Flows are explicit or implicit. An *explicit flow* $x \Rightarrow y$ occurs whenever the operations generating it are independent of the value of x. Assignment statements, I/O statements, and value-returning procedure calls generate explicit flows. An *implicit* flow $x \Rightarrow y$ occurs whenever a statement specifies a flow from some arbitrary z to y, but execution depends on the value of x. Consider, for example, the statements

$y := 1$; **if** $x = 0$ **then** $y := 0$,

where x is either 0 or 1. On termination of these statements, $x = y$ whether or not the **then** clause was executed. Hence the **if** statement causes an implicit flow $x \Rightarrow y$. In general, all conditional structures generate implicit flows.

It should be noted that the relation $\Rightarrow$ is transitive, that is, $x \Rightarrow y \Rightarrow z$ implies $x \Rightarrow z$. If $x \Rightarrow y$ because some function having x as an operand stores its result in y, the flow is *direct*; otherwise it is *indirect*. An assignment "$y := f(\ldots, x, \ldots)$" thus causes flow $x \Rightarrow y$ directly, while the pair "$z := f(\ldots, x, \ldots); y := g(\ldots, z, \ldots)$" causes flow $x \Rightarrow y$ indirectly.

2.3 Security Requirements

A program p is *secure* if and only if no execution of p results in a flow $x \Rightarrow y$ unless $\underline{x} \rightarrow \underline{y}$. A necessary and sufficient condition for the security of p is then

$$x \Rightarrow y \text{ for some execution of } p \text{ only if } \underline{x} \rightarrow \underline{y}. \qquad (1)$$

Unfortunately condition (1) is generally undecidable. Any procedure purported to decide it could be applied to the statement

if $f(x)$ halts **then** $y := 0$

Fig. 1. Linear priority lattice.

Description	Precedence graph
$S = \{0, 1, \ldots, n-1\}$	n
$i \rightarrow j$ iff $i \leq j$	$n-1$
$i \oplus j = \max(i, j)$	$\vdots$
$i \otimes j = \min(i, j)$	1
$L = 0, H = n-1$	0

Fig. 2. Property lattice for $n = 3$.

Description	Precedence graph
$S = \{000,001, \ldots, 111\}$ $A \rightarrow B$ iff $\mathrm{OR}(A, B) = B$ $A \oplus B = \mathrm{OR}(A,B)$ $A \otimes B = \mathrm{AND}(A,B)$ $L = 000, H = 111$	
and thus provide a solution to the halting problem for an arbitrary recursive function [24]. (In a related study, Harrison, Ruzzo, and Ullman have shown that, without severe restrictions, protection systems contain intractable, if not undecidable, accessing questions [16]).

The undecidability is removed if we replace (1) with the security condition

$$x \Rightarrow y \text{ is specified by } p \text{ only if } \underline{x} \rightarrow \underline{y}. \tag{2}$$

The previous **if** statement can clearly be tested for this condition. However, security condition (2) gives less precision in program certification than (1). For example, consider the program

if $x = 0$ **then if** $x \neq 0$ **then** $y := z$

and a flow relation that disallows only $z \Rightarrow y$. This program is secure by (1) since no execution of it can result in $z \Rightarrow y$, but it will not be certified by a mechanism based on (2) since it specifies $z \Rightarrow y$. There is no reason to believe that loss of precision is avoidable; Jones and Lipton, for example, have shown that it is not even possible to construct a mechanism that rejects exactly the insecure executions of a program [19].

The certification mechanism to be presented is based on condition (2). It determines whether a given program specifies invalid flows, irrespective of whether the program can ever execute them.

3. The Certification Mechanism

When the security classes of variables are declared in a program and are static, it is easy to incorporate the certification process into the analysis phase of a compiler. The mechanism will be presented in the form of *certification semantics*—actions for the compiler to perform, along with usual semantic actions such as type checking and code generation, when a string of a given syntactic type is recognized. This procedure differs from an information tracing procedure given by Moore [25]; ours verifies program flows against a standard, whereas Moore's seeks primarily to construct a flow graph.

When external objects, such as files and separately compiled procedures, are bound to a program, the linker must verify that the actual security class of each such object corresponds properly to the security class declared formally for it in the program. This must be done before a program is executed.

The certification mechanism exploits lattice properties for efficiency. The transitive flow relation implies that sequences of secure direct flows are secure and hence the semantics need only certify the direct flows implied by each syntactic type. The least upper and greatest lower bound properties greatly simplify the amount of information needed to track the origins and destinations of flows. Suppose $x_1, \ldots, x_m$ are sources of information for some receiving object y, as in an assignment statement "$y := f(x_1, \ldots, x_m)$" or in an output statement "**output** $x_1, \ldots, x_m$ **to** y." Rather than certify $\underline{x}_i \rightarrow \underline{y}$ separately for each i, the compiler may form $A = \underline{x}_1 \oplus \cdots \oplus \underline{x}_m$ as the source objects are recognized, and verify simply $A \rightarrow \underline{y}$—only a single internal variable representing the maximal class of the source objects is needed. Now, suppose $y_1, \ldots, y_n$ are to receive information derived from some source object x, as in an input statement "**input** $y_1, \ldots, y_n$ **from** x," or in a structure generating implicit flows from an object x in a conditional expression to objects y_j in that structure's scope. Rather than certify $\underline{x} \rightarrow \underline{y}_j$ *separately for each* j, *the compiler may form* $B = \underline{y}_1 \otimes \cdots \otimes \underline{y}_n$ as the receiving objects are being recognized and verify simply $\underline{x} \rightarrow B$—only a single internal variable representing the minimal class of the receiving objects is needed.

The presentation of the full mechanism has been divided into four parts: (a) assignment, I/O, and simple control structures; (b) general control structures and complex data structures; (c) procedure calls; and finally (d) exception handling.

3.1 Assignment, I/O, and Simple Control Structures

We consider a programming language that supports only the elementary data types **integer**, **Boolean**, and **file**. Extensions to other types are straightforward. Arithmetic and Boolean expressions are formed from variables and constants as in Pascal [31]. The control structures specify assignment, input and output with files, selection (by an **if** statement), and iteration (by a **while** statement). A program comprises a list of declarations, including security class declarations, followed

25	**end**	

by the executable statements. An example program is given in Figure 3(a).

Table I gives the syntax and certification semantics for this language. To avoid ambiguities in the semantics, multiple occurrences of the same syntactic type are distinguished (e.g. ⟨*x*⟩, ⟨*x*⟩$_1$, and ⟨*x*⟩$_2$). The security class of a syntactic type ⟨*x*⟩ is denoted by $\underline{\langle x \rangle}$. A compiler variable, CERTIFIED, is initialized to **true** and set to **false** if the compiler ever detects a flow specification violating the flow relation. A program is certified as secure if and only if CERTIFIED = **true** after the entire program has been analyzed. The reader is referred to Gries [15, Sec. 12.2] for an exposition of additional semantic actions, e.g. code generation, that must be defined to complete the compiler.

Figure 4 illustrates the certification of a simple assignment "*c* := *a**2 + *b*". The overall parse can be represented as a syntax tree for the statement. The security classes (in parentheses) are shown opposite each subtree. The semantic actions in effect propagate the security classes of expressions up the tree and verify the flow when the assignment operator is accounted for at the top.

Figure 3(b) shows the certification actions for the example program. When the selection and iteration statements are recognized (lines 20 and 22), the implicit flows from the controlling expressions (the $\oplus$ of the operand classes) to the variables receiving flows in their scopes (the $\otimes$ of all such variable classes) are checked. The example program is certified.

The correctness of the certification semantics is straightforwardly established. Let $x_1, \ldots, x_m$ denote the operands (source objects) in an ⟨exp⟩ or an ⟨outlist⟩, and $y_1, \ldots, y_n$ the results (receiving objects) in an ⟨inlist⟩ or ⟨stmt⟩. From Table I, it is easy to deduce that

$$\underline{\langle \text{exp} \rangle} = \underline{\langle \text{outlist} \rangle} = \underline{x}_1 \oplus \cdots \oplus \underline{x}_m, \tag{p1}$$

$$\underline{\langle \text{inlist} \rangle} = \underline{\langle \text{stmt} \rangle} = \underline{y}_1 \otimes \cdots \otimes \underline{y}_n. \tag{p2}$$

We wish to prove:

THEOREM. *A program is certified only if it is secure.*

The proof is an induction on the structure index *i* of a given program *p*; *i* is simply the number of ⟨stmt⟩ nodes in a syntax tree for *p*. As a basis, consider *i* = 1. There are three cases for the single simple ⟨stmt⟩ constituting *p*.

(1) Suppose ⟨stmt⟩ = "⟨var⟩ := ⟨exp⟩." Let $x_1, \ldots, x_m$ denote the operands of ⟨exp⟩; by (p1), $\underline{\langle \text{exp} \rangle} = \underline{x}_1 \oplus \cdots \oplus \underline{x}_m$. The program is certified only if ⟨exp⟩ → ⟨var⟩ (rule 20) and thus only when it is secure.

(2) Suppose ⟨stmt⟩ = "**input** ⟨inlist⟩ **from** ⟨file⟩." Let $\underline{y}_1, \ldots, \underline{y}_n$ denote the variables in ⟨inlist⟩; by (p2), $\underline{\langle \text{inlist} \rangle} = \underline{y}_1 \otimes \cdots \otimes \underline{y}_n$. The program is certified only if ⟨file⟩ → ⟨inlist⟩ (rule 23) and thus only when it is secure.

(3) Suppose ⟨stmt⟩ = "**output** ⟨outlist⟩ **to** ⟨file⟩." Let $x_1, \ldots, x_m$ be all the objects in ⟨outlist⟩; by (p1), $\underline{\langle \text{outlist} \rangle} = \underline{x}_1 \oplus \cdots \oplus \underline{x}_m$. The program is certified only if ⟨outlist⟩ → ⟨file⟩ (rule 26) and thus only when it is secure. Thus the theorem holds for all programs of one simple statement.

As an induction hypothesis, assume that the theorem holds whenever the program's structure index sat-

Table I. Basic Certification Semantics.

isfies $1 \leq i < J$ and consider a program p for which $i = J$. There are two cases:

(1) p is a compound statement of the form ⟨stmt⟩ = "**begin** ⟨stlist⟩ **end**." The semantics assume that ⟨stmt⟩ is certified whenever ⟨stlist⟩ is (rule 29). Since ⟨stlist⟩ denotes a sequence of statements each with index not exceeding $J - 1$, and since the transitivity of the flow relation implies that any sequence of secure flows is secure, ⟨stmt⟩ is secure when ⟨stlist⟩ is.

(2) p is a selection or iteration statement of the form ⟨stmt⟩ = "**if** ⟨exp⟩ **then** ⟨stmt⟩$_1$ [**else** ⟨stmt⟩$_2$]" or "**while** ⟨exp⟩ **do** ⟨stmt⟩$_1$." Let $x_1, \ldots, x_m$ be the operands of ⟨exp⟩; by (p1), $\underline{\langle exp \rangle} = \underline{x}_1 \oplus \cdots \oplus \underline{x}_m$. Let $y_1, \ldots, y_n$ be the objects receiving flows specified by ⟨stmt⟩$_1$ [and ⟨stmt⟩$_2$]; by (p2) and rule 30, $\underline{\langle stmt \rangle} = \underline{\langle stmt \rangle_1}$ [$\underline{\langle stmt \rangle_2}$] $= \underline{y}_1 \otimes \cdots \otimes \underline{y}_n$. By induction ⟨stmt⟩$_1$ [and ⟨stmt⟩$_2$], having structure indices not exceeding $J - 1$, are certified only if secure. However, rules 30 and 31 certify ⟨stmt⟩ only if $\underline{x}_1 \oplus \cdots \oplus \underline{x}_m \rightarrow \underline{y}_1 \otimes \cdots \otimes \underline{y}_n$, and thus only when the selection or iteration statement

is secure. This completes the correctness proof of the certification semantics.

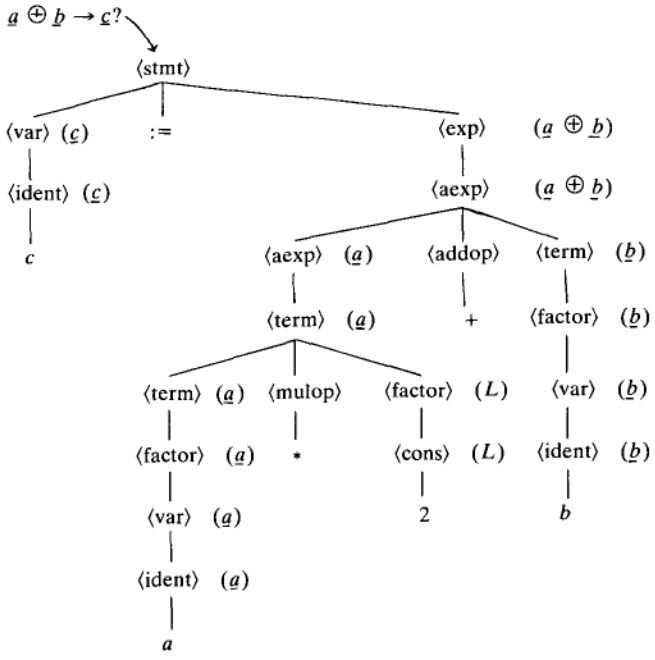
3.2 General Control and Data Structures

The method of certifying the **if** and **while** statements can be extended to any selection or iteration structure expressible as a single statement. This includes, for example, the Pascal **repeat**, **for**, and **case** statements [31]. The principle is to identify the operands $x_1, \ldots, x_m$ of the controlling expression and the objects $y_1, \ldots, y_n$ receiving flows within the scope of the structure and then verify that $\underline{x}_1 \oplus \cdots \oplus \underline{x}_m \rightarrow \underline{y}_1 \otimes \cdots \otimes \underline{y}_n$.

This technique can be extended to control structures arising from arbitrary **goto** statements. However, certifying a program with unrestricted **goto**s requires a control flow analysis of the program to determine the objects receiving flows within the scope of a conditional expression. (This analysis is unnecessary if **goto**s are restricted—e.g. to loop exits—so that the scope of conditional expressions can be determined during syntax analysis.) Following is an outline of the analysis required to do the certification. All *basic blocks* (single-entry, single-exit substructures) are identified. A *control flow graph* is constructed, showing transitions among basic blocks; associated with block b_i is an expression e_i that selects the successor of b_i in the graph. (How to do this is detailed in [1, 22]). The security class of block b_i is the greatest lower bound of the security classes of all objects receiving flows in b_i (if there are no such objects, this class is H). The *immediate forward dominator* $IFD(b_i)$ is computed for each block b_i; it is the closest block to b_i among the set of blocks which lie on all paths from b_i to the program exit. Define B_i as the set of all blocks on some path from b_i to $IFD(b_i)$. The security class $\underline{B}_i$ is the greatest lower bound of the classes of blocks in B_i. Since the only blocks directly conditioned on the selector expression e_i of b_i are those in B_i, the program is secure if each block b_i is independently secure and $\underline{e}_i \rightarrow \underline{B}_i$ for all i. Full details of this procedure, with examples, are given in [6].

The mechanism can also be extended to handle complex data structures. We shall consider arrays and records to illustrate the method; Table II shows the semantics. We assume that, just as they are of the same data type, the elements of an array are of the same security class. The certification semantics specify that, as an array reference is processed, the classes of the subscripts should be joined with that of the array, yielding a class $\langle \underline{\text{array ref}} \rangle = \langle \underline{\text{ident}} \rangle \oplus \langle \underline{\text{sublist}} \rangle$ (rule 35). This is sufficient as long as the array reference is a source object in an expression. If, however, the array reference is a receiving object, e.g. on the left side of an assignment statement, the relation $\langle \underline{\text{sublist}} \rangle \rightarrow \langle \underline{\text{ident}} \rangle$ must also be verified because information about the subscripts flows into the array in this case—e.g. after the assignment "$a[i] := 1$" is made on an all-zero array,

Fig. 4. Certification tree of an assignment statement.



the value of i can be deduced by searching for the first nonzero element. Since $\langle \underline{\text{array ref}} \rangle = \langle \underline{\text{ident}} \rangle \oplus \langle \underline{\text{sublist}} \rangle$ is computed for any array reference (rule 35), and since then $\langle \underline{\text{sublist}} \rangle \rightarrow \langle \underline{\text{ident}} \rangle$ implies $\langle \underline{\text{sublist}} \rangle \oplus \langle \underline{\text{ident}} \rangle = \langle \underline{\text{ident}} \rangle$, this check reduces to testing whether $\langle \underline{\text{array ref}} \rangle = \langle \underline{\text{ident}} \rangle$ when ⟨array ref⟩ is recognized as receiving a flow. We have not shown this check in the certification tables.

As a general rule, certification semantics must generate code that verifies whether computed addresses refer to the objects assumed during certification. Thus the array semantics must verify that the subscripts select elements in the declared range of the array (rule 35). Without this, a statement like "$a[i] := b$" might cause an invalid flow $b \Rightarrow c$, where c is an object addressed by $a[i]$ when i is out of range.

A record r is a structure comprising fields $x_1, \ldots, x_m$, the ith element being referenced by the compound name $r.x_i$. Having a distinct name, each element can be assigned to a different security class. The notation $\oplus\underline{r}$ denotes $\underline{r.x}_1 \oplus \cdots \oplus \underline{r.x}_m$; $\otimes r$ is similarly defined. An operation copying a record from a file f into r is secure only if $\underline{f} \rightarrow \otimes\underline{r}$. An operation copying a record r into a file f is secure only if $\oplus\underline{r} \rightarrow \underline{f}$. An assignment "$r := s$" for two records of identical structure is secure only if $\underline{s.x}_i \rightarrow \underline{r.x}_i$ for each i. (A stronger, but not equivalent, requirement $\oplus\underline{s} \rightarrow \otimes\underline{r}$ would be easier to implement.)

3.3 Procedure Calls

A program p is secure only if it calls certified procedures for which the linkage flows are secure. Let q be a procedure with formal input parameters $x_1, \ldots, x_m$

and formal output parameters $y_1, \ldots, y_n$. Consider a call to q in p of the form

call $q(a_1, \ldots, a_m; b_1, \ldots, b_n)$,

where $a_1, \ldots, a_m$ are taken as the actual input parameters and $b_1, \ldots, b_n$ as the actual output parameters of the call. The security of the call requires that three conditions be verified:

(a) q is secure,
(b) $\underline{a}_i \rightarrow \underline{x}_i$ for $i = 1, \ldots, m$, and
(c) $\underline{y}_j \rightarrow \underline{b}_j$ for $j = 1, \ldots, n$.

Should the **call** statement appear in the scope of conditional expressions $e_1, \ldots, e_k$, the implicit flows from $e_1, \ldots, e_k$ to objects that could receive values during execution of q must be verified. To this end, the compiler of q must identify all objects $c_1, \ldots, c_l$ to which q specifies flows; among them will be the formal output parameters of q. The security of the **call** statement requires that

(d) $\underline{e}_1 \oplus \cdots \oplus \underline{e}_k \rightarrow \underline{c}_1 \otimes \cdots \otimes \underline{c}_l$.

If (d) is verified, then by (c) $\underline{e}_1 \oplus \cdots \oplus \underline{e}_k \rightarrow \underline{y}_j \rightarrow \underline{b}_j$ for each actual output b_j of q.

Unless p and q are compiled together, conditions (a)-(d) cannot be verified at the same time. However, the certifier can output into the separately compiled p and q information used subsequently by a linker to certify the linkage flows. On recognizing a call to q in p, the certifier outputs the list of $m + n + 1$ classes $(\underline{a}_1, \ldots, \underline{a}_m; \underline{b}_1, \ldots, \underline{b}_n; \underline{e}_1 \oplus \cdots \oplus \underline{e}_k)$. For procedure q, it outputs the list of $m + n + 1$ security classes $(\underline{x}_1, \ldots, \underline{x}_m; \underline{y}_1, \ldots, \underline{y}_n; \underline{c}_1 \otimes \cdots \otimes \underline{c}_l)$. By matching these lists, the linker can verify conditions (b)-(d).

This mechanism permits constructing a procedure q which outputs results of a higher class than the inputs. This is convenient when q itself, or confidential information used by q to compute its results, must be protected. The flow of information computed by q can be restricted to actual outputs of high security classes.

The foregoing approach poses a serious limitation in designing a procedure q for handling arbitrary classes of information, as is typical of library procedures. The formal inputs $x_1, \ldots, x_m$ must be declared in the highest security class H so that $\underline{a}_i \rightarrow \underline{x}_i$ $(i = 1, \ldots, m)$ can be verified for all calls. This implies that $y_1, \ldots, y_n$ must also be declared in H since they will be derived from $x_1, \ldots, x_m$. This in turn implies that no cell on q can be verified unless the caller has assigned $b_1, \ldots, b_n$ to H, even if $a_1, \ldots, a_m$ are all in the least class L. The foregoing mechanism cannot therefore be used to contruct unrestricted procedures that yield low security results from data in arbitrary security classes.

One solution, analogous to the PL/I GENERIC procedure for different data types [17], is to prepare a separate version of q for each possible combination of input security classes. The viability of this approach is questionable when there are many possible combinations of parameter security classes. A more attractive solution results when q is restricted in two ways: Its output parameters are derived solely from the input parameters and information in the least class L; it is not permitted to write into any other nonlocal objects. (Local objects can be written if their values are erased when q returns.) The security of a call on such a restricted procedure is verified whenever

(a) $\underline{a}_1 \oplus \cdots \oplus \underline{a}_m \rightarrow \underline{b}_1 \otimes \cdots \otimes \underline{b}_n$, and
(b) $\underline{e}_1 \oplus \cdots \oplus \underline{e}_k \rightarrow \underline{b}_1 \otimes \cdots \otimes \underline{b}_n$.

Table III gives the semantics for certifying these conditions. Note that condition (b) is verified by assigning the class $\underline{b}_1 \otimes \cdots \otimes \underline{b}_n$ to the node of the syntax tree associated with the **call** statement so that the implicit flow is handled in the same way as in other statements.

A special case of these restricted procedures is the "function" type procedure (e.g. SORT, LOG, SIN).

Table II. Certification of Arrays and Records.

Syntax rule	Certification semantics
Arrays	
33 ⟨sublist⟩ ::= ⟨exp⟩	⟨sublist⟩ := ⟨exp⟩
34 ⟨sublist⟩ ::= ⟨sublist⟩$_1$, ⟨exp⟩	⟨sublist⟩ := ⟨sublist⟩$_1$ ⊕ ⟨exp⟩
35 ⟨array ref⟩ ::= ⟨ident⟩ [⟨sublist⟩]	⟨array ref⟩ := ⟨ident⟩ ⊕ ⟨sublist⟩ generate subscript range checking code
Records	
36 ⟨stmt⟩ ::= **input** ⟨rec⟩ **from** ⟨file⟩	⟨stmt⟩ := ⊗ ⟨rec⟩ if not (⟨file⟩ → ⟨stmt⟩) then CERTIFIED := **false**
37 ⟨stmt⟩ ::= **output** ⟨rec⟩ **to** ⟨file⟩	⟨stmt⟩ := ⟨file⟩ if not (⊕ ⟨rec⟩ → ⟨stmt⟩) then CERTIFIED := **false**
38 ⟨stmt⟩ ::= ⟨rec⟩$_1$:= ⟨rec⟩$_2$	if ⟨rec⟩$_1$ and ⟨rec⟩$_2$ have corresponding elements $x_1, \ldots, x_n$ then if not (⟨rec⟩$_1 \cdot x_i$ → ⟨rec⟩$_2 \cdot x_i$ for all i) then CERTIFIED := **false** ⟨stmt⟩ := ⊗ ⟨rec⟩$_1$ else TYPE ERROR := **true**

Table III. Certification of Restricted Procedure Calls.

Syntax rule	Certification semantics
39 ⟨inparams⟩ ::= ⟨exp⟩	$\underline{\langle \text{inparams} \rangle} := \underline{\langle \text{exp} \rangle}$
40 ⟨inparams⟩ ::= ⟨inparams⟩$_1$, ⟨exp⟩	$\underline{\langle \text{inparams} \rangle} := \underline{\langle \text{inparams} \rangle_1} \oplus \underline{\langle \text{exp} \rangle}$
41 ⟨outparams⟩ ::= ⟨var⟩	$\underline{\langle \text{outparams} \rangle} := \underline{\langle \text{var} \rangle}$
42 ⟨outparams⟩ ::= ⟨outparams⟩$_1$, ⟨var⟩	$\underline{\langle \text{outparams} \rangle} := \underline{\langle \text{outparams} \rangle_1} \otimes \underline{\langle \text{var} \rangle}$
43 ⟨stmt⟩ ::= **call** ⟨ident⟩ ((inparams); ⟨outparams⟩)	if not $\underline{\langle \text{inparams} \rangle} \rightarrow \underline{\langle \text{outparams} \rangle}$ then CERTIFIED := **false** $\underline{\langle \text{stmt} \rangle} := \underline{\langle \text{outparams} \rangle}$
44 ⟨fncall⟩ ::= ⟨ident⟩ ((inparams))	$\underline{\langle \text{fncall} \rangle} := \underline{\langle \text{inparams} \rangle}$
45 ⟨factor⟩ ::= ⟨fncall⟩	$\underline{\langle \text{factor} \rangle} := \underline{\langle \text{fncall} \rangle}$

Here a procedure f is called during expression evaluation (e.g. by $f(a_1, \ldots, a_m)$) and returns with a single result derived entirely from the input parameters and constants. Since there are no explicit output parameters, the function call can be treated as any other expression with operands $a_1, \ldots, a_m$. Table III shows the syntax and semantics for this case.

3.4 Exception Handling

Program traps caused by exceptional conditions—underflow, overflow, divide by zero, array subscript range, endfile, and so forth—require special care [12]. They may cause statements subsequently executed to depend on the variables that caused them. The resulting flows will not be detected by the mechanism defined so far.

The program in Figure 5 will be certified by our mechanism. A problem arises when sum overflows and the trap handler terminates the program: The value of x can be approximated by $MAX/LASTi$, where MAX is the largest value that can be stored in a register and $LASTi$ is the last value of i entered into file f. The trap has effectively caused a flow of class H information (x) into a class L file (f). Had the programmer indicated the possible loop termination by replacing the **while** expression e with "not overflow *sum*," the invalid implicit flow from *sum* to f would have been detected [5].

One solution—inhibit all traps—can be rejected, for it defeats the purpose of traps. Another solution would have the compiler test, for each type of trap possible after each statement, the flow that would arise should that trap occur. This may be rejected for sheer inelegance and impracticality.

A practical solution is based on inhibiting all traps except those for which actions have been defined explicitly by the program. Such definitions could be made with a statement similar to one used in PL/I [17]:

on ⟨condition⟩ ⟨ident⟩ **do** ⟨stmt⟩,

where ⟨conditions⟩ names a trap condition (underflow, overflow, endfile, etc.), ⟨ident⟩ is the identifier to which the condition applies, and ⟨stmt⟩ contains no **gotos**. All **on** statements must appear as part of a program's declaration section. When the trap occurs, ⟨stmt⟩ is executed and control is returned to the point of the trap. Suppose there is an **on** statement "**on** ⟨condition⟩ y **do** ⟨stmt⟩$_1$", z is a variable receiving a flow in ⟨stmt⟩$_1$, another statement ⟨stmt⟩$_2$ in the program contains a reference (either read or write) to y, and ⟨exp⟩ is a conditional expression in whose scope ⟨stmt⟩$_2$ lies. Since ⟨stmt⟩$_1$ is potentially executed immediately after the reference to y in ⟨stmt⟩$_2$, the implicit flow $\underline{\langle \text{exp} \rangle} \rightarrow \underline{z}$ must be verified. To avoid having the compiler backtrack to the **on** statement to verify $\underline{\langle \text{exp} \rangle} \rightarrow \underline{z}$, it is simpler to verify a stronger condition: $\underline{y} \rightarrow \underline{z}$ when the **on** statement is processed, and $\underline{\langle \text{exp} \rangle} \rightarrow \underline{y}$ when ⟨stmt⟩$_2$ is processed. This requires a modification in the semantics: the class of any ⟨stmt⟩ is defined as the greatest lower bound of all $\underline{x}$ such that $\underline{x}$ *either* receives a flow, *or* is an **on** condition identifier referenced, in ⟨stmt⟩. Only those traps for which **on** statements have been declared will be enabled by the compiler.

The program in Figure 5 would be (trivially) certified by this mechanism since it would run with traps inhibited. Had the programmer made clear his intentions via the statement "**on** overflow *sum* **do** e := **false**," the program would not be certified.

4. Applications

4.1 The Confinement Problem

A service procedure is *confined* as long as the system guarantees that it can neither retain *any* customer information nor encode it into any value transmitted by a storage object [20, 21]. It is *selectively confined* if this restriction applies only to confidential customer information [5, 10]. Mechanisms enforcing varying degrees of confinement exist or have been proposed [2, 14, 18, 20, 26, 27].

Our certifier is capable of verifying the partial, or total, confinement of a procedure (see Section 3.3). Let p be a procedure with input parameters $x_1, \ldots, x_c, x_{c+1}, \ldots, x_m$, and suppose that p is permitted to retain information derived from the nonconfidential inputs $x_1, \ldots, x_c$, but not from the confidential inputs $x_{c+1}, \ldots, x_m$. The confinement of p hinges on three properties: (1) p must be internally secure, (2) p must not write into any nonlocal object z for which $\underline{x_i} \rightarrow \underline{z}$ ($c + 1 \leq i \leq m$), and (3) p must invoke only confined procedures. By our definition of security, property (1) implies that confidential information cannot be en-

coded in supposedly nonconfidential results. Property (2) ensures that any information output from p is not derived from confidential inputs. (It does not, however, prevent p from returning confidential results to the customer through the output parameters.) Property (3) requires that p cannot be linked to any other procedure which might violate properties (1) or (2).

4.2 State Variables

Invalid flows ("leaks") can occur in some systems when an observer may examine system state variables and deduce information encoded in them [6, 20, 26]. For example, a process could transmit a confidential value x by locking out files $f_1, \ldots, f_x$; an observer could determine x by counting the number of locked files. These flows can be regulated by associating security classes with all state variables and verifying flows to and from them as with any other object in the system [21].

4.3 Data Bank Confidentiality

Suppose a system (or network of systems) has a large database containing different classes of information about individuals. One class might be employment records, another health records, others credit records, tax records, criminal records, and so on. Assuming that all access to the database must be performed by using certified query and update procedures, controlling flows is straightforward. Let each user u have a *clearance*, i.e. a static security class $\underline{u}$. If u submits a query involving records $x_1, \ldots, x_m$ of the database, the query procedure would verify $\underline{x}_1 \oplus \cdots \oplus \underline{x}_m \rightarrow \underline{u}$ before accepting the request. Similarly, if u submits an update request for records $y_1, \ldots, y_n$, the update procedure would verify $\underline{u} \rightarrow \underline{y}_1 \otimes \cdots \otimes \underline{y}_n$ before accepting the request.

5. Limitations

Lampson has identified three classes of paths, or "channels," by which processes can transmit information out of their immediate environments [20]. *Legitimate channels* are the declared formal outputs of the process; *storage channels* are other storage objects in the nonlocal environment of the process; and *covert channels* are any other transmission methods not involving values stored anywhere in the system. Since the first two channels involve information transmitted through storage objects in the system, their flows can be verified by our mechanism. The third, however, employs physical phenomena to connect events within the computer with those outside; examples include program running time, power consumption, noise, and electromagnetic radiation. Flows along these channels are beyond the pale of our certification mechanism. Various run-time mechanisms must be used to deal with them. Fenton [9, 10] and Jones and Lipton [19], have shown how to construct mechanisms that prevent an isolated program's running time from depending on confidential information. After a careful analysis, Lipner has concluded that sealing covert channels associated with program running time is at best difficult and may be impossible in systems of shared resources [21].

Fig. 5. Program with invalid flow caused by a trap.

```
p: begin
   i: integer security class L;
   e: Boolean security class L;
   f: file security class L;
   x, sum: integer security class H;
   begin
     sum := 0;
     i := 0;
     e := true;
     while e do
       begin
         sum := sum + x;
         i := i + 1;
         output i to f
       end
   end
   end
```

Shifting Garbage Collection Overhead to Compile Time

Jeffrey M. Barth
University of California at Berkeley

This paper discusses techniques which enable automatic storage reclamation overhead to be partially shifted to compile time. The paper assumes a transaction oriented collection scheme, as proposed by Deutsch and Bobrow, the necessary features of which are summarized. Implementing the described optimizations requires global flow analysis to be performed on the source program. It is shown that at compile time certain program actions that affect the reference counts of cells can be deduced. This information is used to find actions that cancel when the code is executed and those that can be grouped to achieve improved efficiency.

Key Words and Phrases: garbage collection, global flow analysis, list processing, optimization, reference counts, storage management
CR Categories: 3.80, 4.12, 4.20, 4.34

Introduction

Heap storage no longer accessible from program variables has traditionally been collected either by garbage collection or by a reference count scheme [5]. Garbage collection involves a periodic disruption of program execution, during which any one of several well-known scan, mark, and collect algorithms can be employed. Reference counting, although less disrup-

* Note. This paper was submitted prior to the time that Horning became editor of the department, and editorial consideration was completed under the former editor, Ben Wegbreit.
